ABSTRACT

In the “Internet of Things” the physical world becomes integrable with computer networks. Embedded computers or visual markers on everyday objects allows things and information about them to be accessible by software in the virtual world. However, this integration is based on competing standards or hacks and thus requires technical expertise and is time consuming. Following the long tail of Web 2.0 mashups applications, we propose a similar approach for integrating real-world devices to the web, allowing for them to be easily combined with other virtual and physical resources. In this paper we discuss possible integration approaches, in particular how we apply the REST principles to wireless sensor networks and smart objects. We further describe two concrete implementations: on the Sun SPOT platform and on the Plogs wireless energy monitors. Finally, we demonstrate how these two implementations can be used to quickly create new prototypes in a mashup manner.

1. INTRODUCTION

In the last decade, a tremendous progress in the field of embedded systems has given birth to a myriad of tiny computers, where virtually any type of sensors/actuators can be attached. By inter-connecting these devices using low-power wireless communication, a brand new world of possible applications is unveiled. Networks of physically distributed objects would be invaluable tools for monitoring the physical world. Unfortunately, due to lack of standards most projects in this field are based on different - and usually incompatible - software and hardware platforms. Within such an heterogeneous ecosystem of devices, development of simple application still requires extensive skills and time. Besides, for each new deployment a large amount of work must be devoted to reimplement basic functions and application specific user interfaces, which is a waste of resources that could be used by developers to focus on the application logic. For example, developers should be able to quickly build applications only by recombining ready-made building blocks, just like with LEGO bricks.

In spite of the increasing popularity of open source communities, progress in networked devices is still being limited by the lack of clear, standardized, and interoperable communication protocols for real objects. For the realm of the “Internet of Things” to materialize (and be scalable), there is an unmet need for a common language that can be understood by my fridge, your TV set, and her car. The Internet is a stunning example of a global network of computers that interoperate smoothly together in spite of the large amount of different software and hardware platforms available, and there is a growing number of embedded devices that can connect directly to the internet. Based on these observations, we propose to leverage the existing and uniquitous Web protocols as common ground where real objects could interact with the Internet. One of the advantages of using Web standards is that devices will be able to finally "speak" the same language as other resources on the Internet, therefore making it very easy to integrate physical devices with any other Web page. Besides, the mashup paradigm has been successfully applied to fast prototype valuable applications, and a similar model for physical computing is missing.

Our contributions in this article is to propose two ways to integrate real-world devices into the existing Web by turning real objects into RESTful resources that can be used directly over HTTP. First, we describe how an actual Web server can be implemented on tiny embedded devices to turn them into RESTful resources. Second, when computational resources are too limited or devices do not offer a RESTful interface, we propose the usage of an intermediate gateway that can offer a unified REST API to access these devices, by hiding the actual communication protocols used to interact with them. Finally, we will illustrate our approach with real prototypes we have built on top of this ecosystem of RESTful devices.

Our main aim is to lay the basis of the future Web of Things. By providing practical guidelines to blend real-world devices into the existing Web, devices and their properties become browsable with any Web browser, with no need for any additional software or driver to be installed. Moreover, simple mashups that combine real-time data from physical devices and other Web content can be built with much less effort than required by existing approaches. Just like mashups have significantly contributed to the “democratization” of the Web, we hope that physical mashups will drastically lower the entry barrier for developing home-made...
applications with devices, thus accelerating the acceptance of the Web of Things.

2. RELATED WORK

With advances in computing technology, tiny Web servers can be embedded in most embedded devices [4]. The idea of each thing having its own Web page is appealing because Web pages could be indexed by search engines, then searched and accessed directly from a Web browser. In the Cooltown project [6], each thing, place, and person have an associated Web page with information about them. XJTA was an open network computing platform designed for peer-to-peer computing that can be implemented on all kinds of devices [15], but was an overlay network that did not use the Web in particular. More recently, Web services, have also been used to interconnect devices on top of standard Web protocols [11].

SenseWeb project [5] is a platform for people to share their sensory readings using Web services to transmit data on a central server. Pachube\(^1\) offers a similar community Web site for people to share their sensor and uses more open data formats. These approaches are based on a centralized repository and devices need to be registered before they can publish data, thus are not sufficiently scalable and are more concerned with data storage and retrieval. Prehofer et al. [10] recently proposed an web-based middleware that is similar to our approach, however Internet is used only as a transport protocol.

In most of early Web-based approaches, HTTP is used only to transport data between devices, while HTTP is in fact an application protocol. Projects that specifically focus on re-using the founding principles of the Web as an application protocol are still not common. Creation of devices that are Web-enabled by design, would facilitate the integration of physical devices with other content on the Web. As pointed out in [17], in which case there would be no need for any additional API or descriptions of resource/function. An early gateway system similar to ours has been proposed [13] but was very limited in terms of functionality. The approach found in [14] is the first to our knowledge to take a very similar approach to ours, but mainly focuses on the discovery of devices rather on the functionalities offered by these real-world devices.

3. WEB-ORIENTED INTEGRATION ARCHITECTURE

Realization of a Web of Things requires to extend the existing Web so that real-world objects and embedded devices can blend seamlessly into it. Instead of using the Web protocols merely as a transport protocols, as it is done when using WS-* Web Services, we would like to make devices an integral part of the Web by using the Web as an application layer. For this purpose, we make the functionalities of real-world embedded devices available through a RESTful API accessible over HTTP, as described in Section 3.1. In this paper we propose two alternative methods to enable REST based interaction with embedded devices. In the first one the device is directly made part of the Web (Section 3.2). In the second it is connected through a Smart Gateway (Section 3.3).

3.1 Turning Sensor Nodes into RESTful Resources

The architectural principle that lies at the heart of the Web, namely Representational State Transfer (REST) as defined by Roy Fielding [2], shares a similar goal with more well known integration techniques such as WS-* Web Services (SOAP, WSDL, etc), which is to increase interoperability for a looser coupling between parts of distributed applications. However, the goal of REST is to achieve this in a more lightweight and simpler manner, and focuses on resources, and not fictions as is the case with WS Web services. In particular, REST uses the Web as an application platform and fully leverages all the features inherent to HTTP such as authentication, authorization, encryption, compression, and caching. Moreover, REST brings services “into the browser”: resources can be linked and bookmarked and the results are visible in any Web browser, without the need to generate complex source code out of WSDL files to be able to interact with the service.

To achieve this, REST proposes two basic rules\(^2\):

1. The application model is transformed from operation-centric into a data-centric one. This means “everything” that offers services becomes a resource (e.g. a temperature sensor is a resource of a the sensor node resource) that can be identified unambiguously using a URL.

2. The four main operations provided by HTTP (GET, POST, PUT, DELETE) are the only available operations on resources, they define a uniform interface with well-known and shared semantics.

The simplicity of REST and its seamless integration into global networks makes it an ideal candidate for creating “tactical, ad-hoc integration over the Web” [9]. These advantages mainly explain why REST services are the technological basis for an increasing number of Web 2.0 services such as those offered by Flickr, Twitter, Facebook, Del.icio.us, Google and Amazon. Traditionally, REST has been used to integrate Websites together. However, the lightweight aspect of REST makes it an ideal candidate for resource-constrained embedded devices to offer services to the world [7, 8]. Since many such devices usually offer rather simple and atomic functionalities (for example reading sensor values), modeling them using REST is often straightforward.

3.2 Integration Through Direct API Access

Although REST seems suited for embedded devices, these do not always have an IP (Internet Protocol) address and are thus not directly addressable on the Internet. However, it is very likely that more and more real-world devices will become IP-enabled and have embedded HTTP servers (in particular with 6LowPAN), making them able to understand the Web languages and protocols [4, 1]. Such Web-enabled devices can be directly integrated and make their RESTful APIs directly accessible on the Web. This integration process is shown on Figure 1. Each device has an IP address and runs a Web Server on top of which it offers a RESTful API to the mashup developer.

\(^2\)A comprehensive description of the REST principles and on the creation of Resource Oriented Architectures is provided in [12]

\(^1\)http://www.pachube.com
Each device embeds a Web Server and offers its functionality through a RESTful API.

Figure 1: Direct integration of IP real-world devices. Each device embeds a Web Server and offers its functionality through a RESTful API.

Figure 2: Integration architecture with Smart Gateways making the functionalities of real-world devices available on the Web through a RESTful API.

3.3 Integration Through API Access on Smart Gateways

While such Web-enabled devices are likely to be widely spread in the near future, direct integration of real-world devices into the Web is still a rather cumbersome task. In particular, when devices do not support IP or HTTP as is usually the case with wireless sensor networks (WSN), a different integration pattern is needed. As shown on Figure 2, we propose to use the concept of Smart Gateways as intermediate element that bridges the Web with devices that do not talk IP [16]. Smart Gateways have one main goal: they abstract the proprietary communication protocols or APIs of embedded devices and offer their functionalities accessible via a RESTful API. Each gateway has an IP address and runs a Web server, and understands the proprietary protocols of different devices that are connected to it through the use of dedicated drivers. As an example, consider a request to a sensor node comming from the Web trough the RESTful API, the gateway maps this request to a request in the proprietary API of the node and transmits it using the communication protocol the sensor node understands (e.g. Zigbee³). A Smart Gateway can support several types of devices through a driver architecture as shown on Figure 2 where the gateway supports three types of devices and their corresponding communication protocols. Technical details of the Smart Gateways can be found in [16]. Ideally, a Smart Gateway needs to keep a small footprint so that it can be integrated to computers already present in the environment such as Network Attached Storage (NAS) devices or Wireless routers. As an example we successfully tested the deployment of our gateway on an NSLU2 NAS⁴.

Aside from connecting limited devices to the Web, a Smart Gateway can also add more functionalities to devices. Gateways can be used for orchestrating the composition of several low-level services into higher-level services available from the RESTful API, that is creation of mashups using device-level services. For instance, if an embedded device offers monitoring of the energy consumption of appliances, the Smart Gateway could provide a service that returns the sum of all the energy consumption monitored by all the embedded devices connected to the gateway.

4. IMPLEMENTATION

In order to empirically analyze and test the potential of the RESTful approach for real-world services and how our approach could become the basis for the Web of Things, we implemented the architecture on two WSNs platforms: the Sun SPOT sensor nodes⁵ and the Ploggs Energy Sensors⁶. In this section we describe the architecture of both implementations and then focus on how these were used to create mashups.

4.1 RESTful Ploggs

In our first implementation, we illustrate the usage of a Smart Gateway (see Section 3.3). For this purpose, we use

³http://www.zigbee.org/
⁴http://en.wikipedia.org/wiki/NSLU2
⁵http://www.sunspotworld.com/
⁶http://www.plogginternational.com/
intelligent power outlets called Plogg which can measure the electricity consumption of the devices that are plugged into them. Each Plogg is also a wireless sensor node that communicates over Bluetooth. This makes the Ploggs especially suited for energy monitoring at the appliance level. However, the integration interface offered by the Ploggs is proprietary which makes the development of the applications on top of the Ploggs rather tedious.

The Web-oriented architecture we have implemented using the Ploggs is based on four main layers as shown in Figure 3. The first layer is composed of appliances we want to monitor and control through the system. In the second layer, each of these appliances is then plugged to a Plogg sensor node. In the third layer, the Ploggs are discovered and managed by a Smart Gateway. The Smart Gateway embeds a lightweight Web server which offers the monitoring and control functionalities of the Ploggs through URLs, in a RESTful manner. The last layer is the user interface where the mashup actually occurs and is described in Section 4.3.1.

4.1.1 Ploggs Smart Gateway

The Ploggs Smart Gateway is a component written in C++ whose role is to automatically find all the Ploggs in the environment and make them available as Web resources. The Gateway first discovers the Ploggs on a regular basis by scanning the environment for Bluetooth devices. It then filters the identified devices according to their Bluetooth identifier. The next step is to make their functionalities available though simple URLs, and for that a small footprint Web server is used to enable access to the sensors’ functionalities over the Web. This is done by mapping URLs to native requests on the Plogg Bluetooth API. For instance, http://webofthings.com/energymonitor/ploggs/kitchen is automatically bound by the Gateway to a method that runs a low-level call that first initiates a bluetooth connection, and then connects to the Plogg named KitchenPlogg, and polls the Plogg for reading the current load of energy measured. For URLs to be served on the Web the Gateway embeds a small footprint Web server. After evaluating several options we decided to use Mongoose, a 35 Kb cross-platform Web server.

Beyond discovering the Ploggs and mapping their functionalities to URLs available on the Web, the gateway has two other main features. First, it can offer local mashups or aggregates of device-level services. For example, the Ploggs Smart Gateway offers a service that returns the combined electricity load of all the Ploggs found at any given time. The second feature is that the gateway can represent the output of services on resources in various formats. As is often the case in Resource Oriented Architectures [12] it returns an (X)HTML page by default in order to ensure the browsability of the results. Results can also be returned in a more interoperable format called JSON (JavaScript Object Notation)9. JSON is an alternative to XML often used as an data-interchange format for Web mashups. Since JSON is a lightweight format we believe it is more adapted to devices with limited capabilities. As an example, the monitoring data of all the currently available Ploggs can be retrieved by accessing the following URL: http://webofthings.com/energymonitor/ploggs/*.json

Figure 4: A sample HTTP response sent back to the client. The packet contains the usual HTTP headers (including the HTTP verb or method: GET), as well as a JSON document a body part. For simplicity, only the JSON part is shown.

4.2 RESTful Sun SPOTs

The Sun SPOTs platform is a Wireless Sensor node particularly suitable for rapid prototyping of WSNs applications. Sun SPOTs run a small footprint Java Virtual Machine that enables the nodes to be programmed using the high-level Java programming language (Java Micro Edition CLDC10). The RESTful architecture we designed and implemented for the Sun SPOTs is composed of two main parts, a software stack embedded on each node and a proxy server to forwards the HTTP requests from the Web to the SPOTs.

4.2.1 Embedded Stack

Each Sun SPOT offers a number of sensors (light, temperature, accelerometer, etc.), a number of actuators (digital outputs, leds, etc.) and a number of internal components (radio, battery). The goal of the embedded web server is to make both the sensors and actuators available as REST re-

  ["lightlevel": [80],
   "threshold": [-1, 37]}
}

Figure 6: A sample HTTP request and response exchanged between a client and SPOT. The packet contains the usual HTTP headers (including the HTTP verb or method: GET) as well as a JSON document a body part.

resources. Unlike for the Ploggs’ implementation, we wanted the Sun SPOT nodes to directly provide a RESTful interface (see Section 3.2), without a Smart Gateway that translates REST requests to proprietary protocols. We implemented an embedded HTTP server directly on the Sun SPOT nodes (nanohttpd). The server natively supports the four main operations of the HTTP protocol GET, POST, PUT, DELETE, i.e the main verbs of REST. The HTTP server is deployed on each sensor node, making it an independent and autonomous Web device.

As for the Ploggs, requests for services (i.e. verbs on resources) are formulated using a standard URL. For instance, typing a URL such as http://webofthings.com/spot1/sensors/light in a browser, requests the resource “light” of the resource “sensor” of “spot1” with the verb GET. When the embedded webserver gets such a request it will dispatch it to the corresponding resource handler as shown on Figure 5. The resource then reads the current light level using the native SunSPOT API and sends it to a formatter component. This component formats the results using JSON, and is wrapped into an HTTP packet and sent further to the client. An extract of the resulting HTTP packet is shown on Figure 6. Alternatively, our implementation supports for the results to be distributed asynchronously to a URL when the values exceed a certain threshold configurable through the REST API as well.

4.2.2 Proxy Server

Since Sun SPOTs do not yet support the IP (Internet Protocol) stack we were not able to integrate them completely directly to the Web. Their radio communication is based on the IEEE 802.15.4 standard. The Web is not directly linked to this protocol, thus a proxy that bridges the Web requests (from TCP/IP) and to the devices over the IEEE 802.15.4 link is needed.

Furthermore, to allow mobile mashups, we wanted the nodes to be able to travel from one place to the other, which requires a dynamic discovery process to find new nodes and register their basic information (the MAC address, a short description, their URL). This process is carried out by a discovery component, which broadcasts invitation messages on a regular basis on a dedicated port. On their side, the nodes listen to this port and can decide to subscribe to the broadcasting proxy server. Then, the proxy registers the node’s address and when receiving an HTTP request from the Internet, it reads the request URL and maps it to one of the registered nodes. In case the node is busy, it also serves as a buffer by queuing requests and resubmitting them later. In order to deal with URL and HTTP packets the proxy uses functionalities developed on top of RESTlet, a lightweight REST framework implemented in Java11. We expect 6LowPAN implementations to be available for the SunSPOT soon, thus a proxy will not be needed anymore for connecting the SPOTs to the Internet.

4.3 Mashups in the Web of Things

Based on this substrate of real-world devices that offer a RESTful API, we can now easily integrate the functionalities of both the Sun SPOTs and the Ploggs to easily create new composite applications. We provide in this section two concrete examples of mashups that can be created on top of these embedded devices. We classify these examples in two categories: physical-virtual mashups (also called cyber-physical systems) and physical-physical mashups. In the first category, we present two prototypes of user interfaces running on a computer and consuming services from the real-world. In the second category, we present a prototype of a physical user interface, or ambient user interface that uses services from the real-world.

4.3.1 Physical-Virtual Mashups

In the first example of prototype implementation, we built an AJAX management interface on top of the Sun SPOT RESTful API. In the second example, we create a mashup web UI that can be used to monitor the energy consumption of household appliances.

4.3.1.1 Sun SPOT Resources Manager.

While a minimal presentation requirement for real-world devices in the Web of Things is to offer a (X)HTML interface to browse their resources, it might not always be sufficient. Indeed, the sole HTTP verbs that can easily be used from HTML pages are GET and POST. Furthermore, using the plain HTML interface each page can be browsed to explore the Spots’ resources results in initiating a new communication link with the involved Spots. Since these initializations are rather expensive in terms of battery life, it would be desirable to reduce them as much as possible by having the Spot communicating more data at once and by caching this data on the client side (or on the proxy).

To overcome both these limitations (limited verbs and expensive communication) and illustrate a solution, we build an AJAX (Asynchronous JavaScript and XML) interface on top of the RESTful Sun SPOT API, and is shown on Figure 7. AJAX Web pages present two main advantages in this case. First, they can initiate HTTP calls with any of the HTTP verbs (e.g. with PUT and DELETE). Second, these calls can be executed asynchronously and the results can be displayed only when needed, thus offering a straightforward way of reducing communication with the device. Note that while such an interface is not a mashup per se, it

11http://www.restlet.org/
4.3.1.2 Energy Visualizer.

In this second example we create a mashup that fulfills an increasingly important need for households. Indeed, a major burden for people who want to save energy is to identify how much energy is consumed by home appliances. "How much does my computer consume in operation / when it is powered off or in standby? Is the consumption of my energy-saving lamp significantly lower in the long run than the normal lamp I’ve got there?" Such questions are key to understand where energy can be saved with simple efforts. Currently available solutions, such as traditional LCD power monitors, are helpful but do not really fit the needs of most individuals. They lack demonstrating power such as being able to compare consumption of individual devices into a single place, say a screen or a mobile phone in an appealing and simple manner. Furthermore, they do not offer many options for remote monitoring and control.

The idea of the Energy Visualizer prototype we have built is to offer a dashboard user interface on the Web that enables people to control and experiment with the consumption of their appliances. We wanted the user interface to be attractive, easily accessible (no additional software to learn or install) and to display real-time data about the energy consumption rather than snapshots, thus decided to use a dynamic Web page illustrated in Figure 8. It offers six real-time and interactive graphs. The four graphs on the right side provide detailed information about the current consumption of all the appliances currently in the vicinity of the gateways. The two remaining graphs show the total consumption (kWh), and respectively a comparison (on the same scale) of all the running appliances. Finally, a switch button next to the graphs enables the user to power on and off the devices over the Web.

This dashboard is built as a mashup that uses the RESTful Plogg API in a Google Web Toolkit application. The Google Web Toolkit (GWT) is a great platform for building web mashups since it offers a large number of easily customizable widgets. For the graphs shown on Figure 8, we use the Open Flash Chart GWT Widget Library. This library offers a comprehensive set of graph widgets that are customizable by feeding them JSON documents.

To dynamically draw the graphs according to the current energy consumption, the mashup application calls the Ploggs Smart Gateway every 10 seconds by issuing a GET HTTP request to all the Ploggs

http://webofthings.com/energymonitor/ploggs/*.json

or by requesting the energy consumption of a single Plogg with a GET call to

http://webofthings.com/energymonitor/ploggs/fridge.json

It then feeds the resulting JSON document (shown on Figure 6) to the corresponding graphs. Furthermore, a click on the switch button next to the graphs on Figure 8 can stop the corresponding appliance by sending the following HTTP packet shown on Figure 9. The effect of this call will be to stop delivering power to the device attached to the TV plogg, i.e. in this case it will turn the TV off.

4.3.2 Physical-Physical Mashups

This last prototype demonstrates how real-world services provided by physical devices can be combined together using the underlying technologies of mashups, without even requiring a computer or HTTP browser.

4.3.2.1 Ambient Meter.

The prototype is an ambient device that displays the level of energy consumption of the place it is currently located in by changing its color. It can be taken from one place to the other and adapts to the place it monitors automatically, without the need for human intervention. Depending on the...
total amount of energy consumed in the room it is located in, the Ambient Meter changes its color from very green (i.e. the amount of energy consumed in the room is low) to very red (i.e. a lot of energy is currently consumed in this place).

The Ambient Meter is implemented on a Sun SPOT which uses the Ploggs for energy monitoring as well as the Ploggs Smart Gateway for resolution of its current location. It uses an HTTP connector we implemented in the RESTful Sun SPOT API to contact the RESTful Plogg API. Every 5 seconds, the Ambient Meter will poll the following URL using the GET method on http://localhost/energymonitor/load.json When the meter is located in Room 1, as shown on Figure 10 (step 1) it is bound to the Smart Gateway 1, meaning that localhost in this context is bound to the address of Smart Gateway 1. Thus, the result of the call is going to be the JSON representation of the energy consumption of all the Ploggs discovered by the Ploggs’ Smart Gateway 1. Placed in the hallway, the Ambient Meter binds itself to Smart Gateway 2. Using the same URL as before it will get the energy consumption of all the devices monitored. Again, the same process occurs in Room 2, where the Ambient Meter gets the load of the desktop computer and the lamp. Integrating all the real-world devices of this prototype would have been rather time consuming if the Smart Gateways, the Ploggs and the Sun SPOTs were only offering their native (proprietary) APIs. Thanks to the RESTful approach the integration work was reduced to a building a simple Web mashup, where all the services are invoked by means of simple and lightweight HTTP requests.

5. DISCUSSION AND FUTURE WORK

In this paper we have contribute to a step towards the realization of the Web of Things. By creating RESTful APIs to integrate the services offered by devices and objects in the real world such as wireless sensor networks, embedded devices and household appliances with any other Web con-
tent. We have described two ways to integrate devices to the Web using REST, a direct integration based on the advances in embedded computing and a Smart Gateway-based approach for resource-limited devices. We have further illustrated these methodologies by implementing them on two different platforms. Finally, we show how an eco-system of RESTful devices can facilitate significantly the creation of cyber-physical mashups. In the meanwhile, using REST and the Web to connect devices offers a very flexible and powerful mechanism to fast prototype all kinds of applications.

Still, it is important to note that RESTful services also have certain limitations and do not always solve problems in a straightforward manner. For instance, the inherent simplicity of REST paradoxically complicates the creation of complex services. While REST services are well adapted for simple and atomic services, which cover the greatest part of services available on embedded computers, their limitations become evident when it comes to modeling services which require complex input and/or deliver complex outputs. Based on our own experience and the experience of others [9] in more traditional integration patterns such as WS-* Web Services, we suggest that WS-* services are to be preferred for complex real-world integration and rather static use-cases, such as those involving complicated business processes or requiring high reliability, for example composing a manufacturing process on several machines. However, for smaller and more user-oriented applications, the RESTful approach offers many advantages such as light and simple use, browsability of services, and a much looser coupling. This is for us exactly the type of applications mashups are suited to.

Providing a substrate of RESTful and Web oriented embedded devices is only a step towards a global Web of Things. While we believe it greatly simplifies the development of ad-hoc applications, the RESTful approach also introduces new challenges such as dealing with the vast variety of data formats that HTTP payloads can contain (e.g. XML, JSON, raw ASCII, etc.). Furthermore, as more and more devices will become part of the Web new challenges will appear. Some of these, directly related to mashups are shown on the upper parts of Figures 1 and 2. How will we be able to search amongst an increasing number of dynamic devices, and in particular how will we be able to identify the devices we want to interact with? This point has been identified as a particularly important problem for future ubiquitous environments [3]. Even if real-world devices are to offer Web Servers and Web pages, searching for them is not entirely similar to searching textual information on the Web. In particular, context information such as location, time, type of use is central for searching real-world services. Thus, a scalable dynamic search mechanism that take into account the physicality of real-world services will be necessary. Similarly, building mashups consuming services on the Web is not entirely similar to building mashups consuming real-world services. If we really want end-users to be able to build mashups we need to provide them with higher abstraction such as mashup editors like Microsoft Popfly or Yahoo Pipes adapted to the real-world.

6. ACKNOWLEDGMENTS

The authors would like to thank the European Commission and the partners of the European IST FP6 project “Service-Oriented Cross-layer infrAstructure for Distributed smart Embedded devices” (SOCRADES - www.socrates.eu) for their support. A special thanks goes to Thomas Pham for his work on the Sun SPOT RESTful architecture, to Markus Weiss for his advices on the Energy Visualizer Prototype, and to Samuel Wieland for his help on the Smart Gateway Architecture.

7. REFERENCES
